Prerequis

Ceci est une étude des données de panel avec Markdown.

The **bookdown** package can be installed from CRAN or Github:

La structure de ce rapport est que chaque fichier RMD porte un chapitre et un thème bien spécifique de notre analyse

Nous avions utilisé XeLaTeX pour compiler ce document en PDF.

Introduction

You can label chapter and section titles using {#label} after them, e.g., we can reference Chapter 2. If you do not manually label them, there will be automatic labels anyway, e.g., Chapter 5.

Figures and tables with captions will be placed in figure and table environments, respectively.

```
par(mar = c(4, 4, .1, .1))
plot(pressure, type = 'b', pch = 19)
```

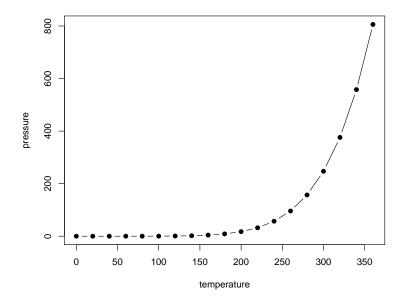

Figure 2.1: Here is a nice figure!

Sepal.Length	Sepal.Width	Petal.Length	Petal.Width	Species

Table 2.1: Here is a nice table!

Reference a figure by its code chunk label with the fig: prefix, e.g., see Figure 2.1. Similarly, you can reference tables generated from knitr::kable(), e.g., see Table 2.1.

```
knitr::kable(
  head(iris, 20), caption = 'Here is a nice table!',
  booktabs = TRUE
)
```

You can write citations, too. For example, we are using the **bookdown** package (Xie, 2021) in this sample book, which was built on top of R Markdown and **knitr** (Xie, 2015).

Literature

The One-way Error Component Regression Model

INTRODUCTION 4.1

A panel data regression differs from a regular time-series or cross-section regression in that it has a double subscript on its variables, i.e.

$$y_{it} = \alpha + X_{it}^{'}\beta + u_{it}$$

$$i = 1,...,N; t = 1,...,T$$

$$(2.1)$$
 with

denoting households, individuals, firms, countries, etc. and t denoting time. The i subscript, therefore, denotes the cross-section dimension whereas t denotes the time-series dimension.

is a scalar, β is $K \times 1$ and Xi t is the it_{th}

12CHAPTER 4. THE ONE-WAY ERROR COMPONENT REGRESSION MODEL

observation on K explanatory variables. Most of the panel data applications utilize a one-way error component model for the disturbances, with

$$u_{it} = \mu_i + v_{it}$$

(2.2)

where i denotes the unobservable individual-specific effect and it denotes the remainder disturbance. For example, in an earnings equation in labor economics, yi t will measure earnings of the head of the household, whereas

 X_{it}

may contain a set of variables like experience, education, union membership, sex, race, etc. Note that i is time-invariant and it accounts for any individual-specific effect that is not included in the regression. In this case we could think of it as the individual's unobserved ability. The remainder disturbance

 v_{it}

varies with individuals and time and can be thought of as the usual disturbance in the regression. Alternatively, for a production function utilizing data on firms across time,

 y_{it}

will measure output and

 X_{it}

will measure inputs. The unobservable firm-specific effects will be captured by the

 μ_i

and we can think of these as the unobservable entrepreneurial or managerial skills of the firm's executives. Early applications of error components in economics include Kuh (1959) on investment, Mundlak (1961) and Hoch (1962) on production functions and Balestra and Nerlove (1966) on demand for natural gas. In vector form (2.1) can be written as

$$y = \alpha i_{NT} + X\beta + u = Z\delta + u$$

(2.3)

$$y = \alpha i_{NT} + X\beta + u = Z\delta + u$$

(2.3)

where

is $NT\times 1$, X is $NT\times K$, $Z=[\iota_{NT},X]$, $\delta'=(\alpha',\beta')$ and $\iota_{N}T$

is a vector of ones of dimension NT. Also, (2.2) can be written as

$$u = Z_{\mu}\mu + v \tag{2.4}$$

 $y_{it} = \alpha + X_{it}^{'} + U_{it}$

, $i=1,\dots,N$; t=1,...,T $\$ with i denoting households, individuals, firms, countries, etc. and t denoting time. The i subscript, therefore, denotes the cross-section dimension whereas t denotes the time-series dimension. $\$ is a scalar, $\$ is $\$ K \times 1 $\$ and $\$ it $\$ is the $\$ it $\$ boservation on K explanatory variables. disturbances, with it

$$u_{it} = u_i + v_{it}$$

where i denotes the unobservable individual-specific effect and νit denotes the remainder disturbance. For example, in an earnings equation in labor economics, y_{it} will measure earnings of the head of the household, whereas Xi t may contain a set of variables like experience, education, union membership, sex, race, etc. Note that i is time-invariant and it accounts for any individual-specific effect that is not included in the regression. In this case we could think of it as the individual's unobserved ability. The remainder disturbance \$ {it} \$ varies with individuals and time and can be thought of as the usual disturbance in the regression. Alternatively, for a production function utilizing data on firms across time, \$y_{it} \$ will measure output and \$X_{it} \$ will measure inputs. The unobservable firm-specific effects will be captured by the \$_i\$ and we can think of these as the unobservable entrepreneurial or managerial skills of the firm's executives. Early applications of error components in economics include Kuh (1959) on investment, Mundlak (1961) and Hoch (1962) on production functions and Balestra and Nerlove (1966) on demand for natural gas. In vector form (2.1) can be written as

$$y = \alpha i_{NT} + X\beta + u = Z\delta + u$$

where y is \$ NT × 1\$, X is $NT \times K$, \$ Z = [i_{NT} , X] \$, \$ ^{'}=({'}, {'}) \$ and i_{NT} is a vector of ones of dimension NT . Also, (2.2) can be written as

$$u = Z_{\mu}\mu + v$$

(2.4)

where \$ u^{'} = (u_{11}, ..., u_{1T}), u_{21}, ..., u_{2T}, ..., u_{1N1}, ..., u_{1NT}) \$ with the observations stacked such that the slower index is over individuals and the faster index is over time. \$ Z_ = IN T \$ where IN is an identity matrix of dimension N, T is a vector of ones of dimension T and \$ \$ denotes Kronecker product. \$ Z_ \$ is a selector matrix of ones and zeros, or simply the matrix of individual dummies that one may include in the regression to estimate the i if they are assumed to be fixed parameters. \$ ^{'} = (_1, ..., _N) \$ and $\nu' = (\nu 11, ..., \nu_{1T}, ..., \nu_{N1}, ..., \nu_{NT})$. Note that

 $Z_Z^{'} = I_N J_T$ where \$ JT \$ is a matrix of ones of dimension T and \$ P = Z (Z^{'} Z)^{-1} Z^{'} \$, the projection matrix on \$ Z_\$, reduces to IN J^T where \$J^T = JT /T \$. P is a matrix which averages the observation across time for each individual, and Q = INT — P is a matrix which obtains the deviations from individual means. For example, regressing y on the matrix of dummy variables Z_{μ} gets the predicted values \$ P_y \$ which has a typical element

4.2 Manque 3 lignes et 2 équations

P and Q are (i) symmetric idempotent matrices, i.e. $P^{'} = P$ and $P^{'} = P$. This means that $\operatorname{rank}(P) = \operatorname{tr}(P) = \mathbb{N}$ and $\operatorname{rank}(Q) = \operatorname{tr}(Q) = \mathbb{N}(T-1)$. This uses the result that the rank of an idempotent matrix is equal to its trace (see Graybill, 1961, theorem 1.63). Also, (ii) P and Q are orthogonal, i.e. PQ = 0 and (iii) they sum to the identity matrix $P + Q = \operatorname{INT}$. In fact, any two of these properties imply the third (see Graybill, 1961, theorem 1.68).

4.3 THE FIXED EFFECTS MODEL

In this case, the i are assumed to be fixed parameters to be estimated and the remainder disturbances stochastic with i t independent and identically distributed \$IID $(0, _v^2)$ \$. The X_{it} are assumed independent of the i t for all i and t. The fixed effects model is an appropriate specification if we are focusing on a specific set of N firms, say, IBM, GE, Westinghouse, etc. and our inference is restricted to the behavior of these sets of firms. Alternatively, it could be a

set of N OECD countries, or N American states. Inference in this case is conditional on the particular N firms, countries or states that are observed. One can substitute the disturbances given by (2.4) into (2.3) to get

$$y = \alpha i_{IT} + X\beta + Z_{\mu}\mu + v = Z\delta + Z_{\mu}\mu + v$$

(2.5)

16CHAPTER 4. THE ONE-WAY ERROR COMPONENT REGRESSION MODEL

Methods

We describe our methods in this chapter.

Les données de panel, ou données longitudinales possèdent les deux dimensions précédentes (individuelle et temporelle). En effet, il est souvent intéressant d'identifier l'effet associé à chaque individu (un effet qui ne varie pas dans le temps, mais qui varie d'un individu à un autre). Cet effet peut être fixe ou aléatoire.

Par conséquent, le modèle en données de panel s'écrit comme un modèle à double indice qui prend la forme suivante :

$$Y_{it} = \alpha_i \sum_{k} \beta_{ki} x_{ki} + \epsilon_{it}$$

avec

$$i:1 \to N$$

et

$$t: 1 \to T$$

La double dimension qu'offrent les données de panel est un atout majeur. En effet, si les données en séries temporelles permettent d'étudier l'évolution des relations dans le temps, elles ne permettent pas de contrôler l'hétérogénéité entre les individus. A l'inverse, les données en coupes transversales permettent d'analyser l'hétérogénéité entre les individus mais elles ne peuvent pas tenir compte des comportements dynamiques, puisque la dimension temporelle est exclue du champ d'analyse.

Ainsi, en utilisant des données de panel, on pourra exploiter les deux sources de variation de l'information statistique : - Temporelle où variabilité intra-individuelle (within) - et individuelle ou variabilité inter-individuelle (Between).

Analyses

Nous faisons *application* des méthodes présentées dans le chapitre précédant pour l'analyse des données de pannel

Avant de passefr à la modélisation, nous ferons une description de nos variables d'interet d'une manière statique : nos prédicteurs et la variables réponses

6.1 Netoyage de la base des données
